
The double life of the X meson

A.D. Polosa

INFN Sez. di Roma 1, P.le A. Moro 2, I-00185 Roma, Italy.
antonio.polosa@roma1.infn.it

Three years have passed since the BELLE discovery of the $X(3872)$, and there are still (at least) two competing interpretations of this particle, which resembles a charmonium but behaves in a dramatic different way from it. Is X a molecule of two D mesons or a compact four-quark state? Are these two pictures really resolvable?

The quantum mechanical intuition can also lead to more refined pictures: the X could be a sort of breathing mode of a charmonium oscillating into a molecule and back.

Other particles have been discovered since then: the $X(3940)$, $Y(3940)$, $Z(3930)$ (amazingly the first two have the same mass and both decay to charmonium but with a different decay pattern to open charm) and $Y(4260)$. The latter also decays into J/ψ and could be an ‘hybrid’ particle (two quarks and a constituent gluon), likely the most experiment-proof interpretation so far.

In this talk I will not try to describe all the experimental facts and theoretical ideas, thoroughly reported and commented elsewhere in the literature. I will rather comment on the first question here raised, namely, how far are molecules, four-quarks or charmonium-molecule oscillating states distinguishable in principle and in the experimental practice? The suspect that the competing scenarios fade into one another could dangerously leave this field in a confused and controversial situation similar to that existing for sub-GeV scalar mesons (and for their super-GeV partners).

1 Sewing Quarks

The prominent decay mode of $X(3872)$ is $X \rightarrow J/\psi \rho$. Several studies conclude that the X cannot be an ordinary $c\bar{c}$ state, even though the J/ψ invokes a charmonium assignation. The next-to-easy interpretations can be: (1) X is a $D\bar{D}^*$ bound object, with the correct 1^{++} quantum numbers. Such a molecule

could decay at the same rate to $J/\psi\rho$ and $J/\psi\omega$, which is actually what surprisingly happens in nature (this was not a prediction though). This molecule lives for a while, until the two heavy quarks get close enough to form a J/ψ , leaving the light quarks free to hadronize to a ρ^0 . (2) X is a four-quark $c\bar{c}q\bar{q}$ meson. The four quarks could be diving in some potential bag but, if so, we should get $\mathbf{3} \otimes \bar{\mathbf{3}} \otimes \mathbf{3} \otimes \bar{\mathbf{3}}$, i.e., 81 particles. This is the obvious problem of exotic structures: a copious number of states is predicted. Moreover such multiquark structures could fall apart and decay at an immense rate (resulting in very broad and experimentally elusive states): at the lowest $1/N_c$ order a propagating state of four quarks in a color-neutral, gauge-invariant combination $q^i \bar{q}_i q^j \bar{q}_j$, is indistinguishable from two freely propagating $q\bar{q}$ mesons. On the other hand, it turns out that quarks (and antiquarks) can be bound in qq ($\bar{q}\bar{q}$) diquarks (anti-). As for the color, a diquark is equivalent to an anti-quark and the anti-diquark is equivalent to a quark. A diquark-antidiquark meson is therefore pretty much the same as an ordinary meson, as for the strong force.

A $\bar{\mathbf{3}}_c$ spin zero diquark is antisymmetric in flavor, $\bar{\mathbf{3}}_f$, because of the Fermi statistics, as long as $q = u, d, s$. Therefore a four-quark system made up of two diquarks involves $\mathbf{3}_f \otimes \bar{\mathbf{3}}_f$ states, 9 states versus the 81 given before (a crypto-exotic) which is much better, although X is a 1^{++} state and two spin zero diquark cannot do the job.

The X should however contain two c quarks. The heavy quark Q is not indistinguishable from q and spin-spin interactions between an heavy quark and a light one are $O(1/M_c)$, so that, even if non-perturbative dynamics tends to favor the formation of a spin zero diquark (as it has been proved by lattice studies focused on light-light diquarks), an heavy-light diquark can be equally well spin zero or one and its flavor group structure is determined by the light quark only. Again 9 states, but with spin one. The other quantum numbers follow easily.

On the other hand, the number of ways of sewing quarks into a four-quark structure is not exhausted by the possibilities just described. Two $\mathbf{3}_c$ quarks can either attract or repel each other in the $\bar{\mathbf{3}}_c$ or $\mathbf{6}_c$ color channels according to the one-gluon exchange model (which qualitatively reproduces the lattice indications). According to the same model, a $\mathbf{6}_c$ diquark and a $\bar{\mathbf{6}}_c$ anti-diquark could form a color neutral object with the *same* binding energy of the $\mathbf{3}_c - \bar{\mathbf{3}}_c$ diquark-anti-diquark. This object looks like the non-abelian analog of a system of two electrons and two protons in some closed region: an H_2 molecule is formed as a result of the binding of two individual hydrogen atoms.

The one-gluon exchange model of the strong interactions in a hadron is just a qualitative oversimplification, yet it gives the feeling of how the molecule and four-quark languages could dangerously be interchangeable¹.

¹ The oscillating $c\bar{c}$ -molecule picture is a smart refinement of the basic molecule description with a stronger adaptability to the sometimes adverse climatic conditions of the experimental situation

2 Tracing differences

Building four-quark mesons made up of two diquarks requires 9 states: charged X 's should be visible, as well as strange X_s states, according to $SU(3)$. An entire spectrum of these states has been calculated. Only one neutral non-strange X has been observed so far; similarly no charged partners of the higher mass X, Y, Z are observed. This is usually addressed as the weakest point in the tetraquark picture. But, (1) even if an attempt to calculate the X mass spectrum in the four-quark picture has been made, it is not at all easy to predict the widths of these nonet states, most of which could turn out to be very broad. (2) $D\bar{D}^*$ molecules could as well occur in 9 states, though it seems that binding potentials can be tuned to account for the 'reduced' observed spectrum.

At any rate, molecules are very loose bound states: consider for example that $m_D + m_{\bar{D}^*} = 3871.3 \pm 0.7$ MeV. Then we can expect that the typical size of such a molecule is $r \sim 1/\sqrt{2M_X E_{\text{bind.}}} \sim 3 - 4$ fm. Charm quarks have to recombine into a J/ψ (kind of ~ 0.25 fm object) starting from a configuration in which they are up to 4 times the typical range of strong interactions apart. In the tetraquark picture, instead, the c quarks are as close to each other as two quarks in a standard meson.

A $D\bar{D}^*$ molecule should have a decay width $X \rightarrow D^0 \bar{D}^0 \pi^0$ comparable to the $\Gamma(D^* \rightarrow D\pi) \sim 70$ KeV width. This decay mode has been very recently observed to occur at a rate about nine times larger than the $J/\psi\rho$ mode, in bold contradiction with the basic molecular picture where $J/\psi\rho$ was predicted to be by far the dominant one. The tetraquark X is allowed to decay $X \rightarrow D^0 \bar{D}^0 \pi^0$ with a rate almost two times larger than the $J/\psi\rho$. This experimental fact, if confirmed, seriously challenges both models.

All these semi-quantitative considerations are not definitive in deciding neatly between the two options: molecule or tetraquark?. In many respects one could so far object that the two scenarios seem quite contiguous. But, in the tetraquark picture the $X(3872)$ has a 'double life', two different X 's are required (call them X_l and X_h) to account for the observed isospin violation: $\mathcal{B}(X \rightarrow J/\psi\rho)/\mathcal{B}(X \rightarrow J/\psi\omega) = 1.0$. In what follows I will sketch the latter point.

Consider the states $X_u = [cu][\bar{c}\bar{u}]$ and $X_d = [cd][\bar{c}\bar{d}]$, where the square parentheses indicate a diquark binding. The B^+ could decay as $B^+ \rightarrow K^+ X_u$ and $B^+ \rightarrow K^+ X_d$ with some undetermined relative frequency. Let us call A_1 and A_2 the two decay amplitudes. Data on the production of $X(3872)$ in $B^+ \rightarrow K^+ X$ reasonably show that only one single state is produced in this channel. Therefore either $A_1 \gg A_2$ or $A_1 \ll A_2$. Whatever the actual situation is, a naive quark analysis shows that in $B^0 \rightarrow KX$, A_1 and A_2 would be interchanged: if X_u is produced in B^+ decay, then X_d is produced in B^0 decay and vice-versa.

Actually, the real X 's can be superpositions of X_u and X_d . In a standard mixing scheme we can introduce two orthogonal superpositions, X_l and X_h ,

mixed by an angle θ . The annihilation diagrams describing $u\bar{u} - d\bar{d}$ transitions are reasonably quite small at the m_c scale so that we expect θ to be small. X_l and X_h are therefore unbalanced superpositions of $I = 1/2$ and $I = -1/2$ states (at $\theta = \pi/4$, X_l and X_h are $I = 0$ and $I = 1$ respectively; X_l could, e.g., only decay to $\omega J/\psi$) opening the way to isospin violations in the decays of X_l and X_h . On the other hand the $D\bar{D}^*$ molecule is per-se a single isospin impure state.

X_l and X_h are expected to have a difference in mass, ΔM , proportional to $(m_d - m_u)$ and inversely proportional to $\cos\theta$ (which can be fixed by decay data). Such a mass difference is under experimental study (the mass of the X produced in B^+ is confronted to the mass of X produced in B^0) but the error on data still does not allow to draw a definitive conclusion. A $\Delta M \sim O(1)$ MeV would clearly unveil the double life of X excluding the molecule (and all the way around).

Resolving this molecule-tetraquark dichotomy is not only a matter of taxonomy. Diquarks have an interesting role in QCD. An entire region of the QCD phase diagram in the (μ, T) plane has been found to exist in a phase of color superconductor where the analogous of the ordinary Cooper pairs are diquarks. Diquarks also enter in diverse QCD considerations. Just to mention one, recall for example the argument to explain the limit $F_2^n/F_2^p \rightarrow 1/4$ as $x \rightarrow 1$ of the DIS structure functions of neutron and proton. Diquarks could also help to explain the fact that the Regge trajectories of mesons and baryons happen to have the same slope.

3 Counting Quarks

Obtaining direct experimental evidence that the X is a multiquark object would certainly be rather useful. A new method to investigate the quark nature of the X and of all those states missing a clear quark-identikit, like $f_0(500)$, $a_0(980)$, $f_0(980)$..., could be obtained by the analysis of certain heavy-ion collision observables.

A stunning fact emerged at RHIC is that the number of protons divided by the number of pions counted in a $p_\perp$ region $1.5 \text{ GeV} \leq p_\perp \leq 4 \text{ GeV}$ is ≥ 1 , against any expectation based on fragmentation functions which would predict an opposite pattern. In such experimental situation, fragmentation is insufficient at producing high $p_\perp$ hadrons. In the standard fragmentation picture, an off-shell parton loses energy via a perturbative ‘shower’ of gluon emissions until the energy scale of Λ_{QCD} is approached, where the non-perturbative domain opens. At this stage all the partons formed will get together in separated clusters tending to neutralize the color and generating, via some non-perturbative mechanism, a collection of real hadrons. The energy of the initial parton is repartitioned among all the final state hadrons produced. High $p_\perp$ hadrons in the final state must be originated by very high $p_\perp$ initial partons which, in usual conditions, are not abundantly produced: pQCD spectra are

steeply falling with $p_\perp$. Moreover, the standard fragmentation function approach predicts that, for a generic parton a , $D_{a \rightarrow p}/D_{a \rightarrow \pi} \leq 0.2$ in the above $p_\perp$ range.

But, suppose that a rapidly expanding state, overflowed in phase space with partons, is created in a heavy-ion collision. Neighboring partons in phase space could be able to recombine into hadrons whose momenta are just the algebraic sums of the parton momenta involved. In this case we could state that $[p \text{ spectrum}] \sim \exp[-p_\perp^{(a)}/3]^3 \approx [\pi \text{ spectrum}] \sim \exp[-p_\perp^{(a)}/2]^2$, $p_\perp^{(a)}$ being a parton momentum; this is the essential point about the so called ‘coalescence’ picture.

Attempts have been made to devise models of fragmentation/coalescence (f/c) and to calculate the $p_\perp$ dependence of certain experimental observables. One of these observables, the so called ‘nuclear modification ratio’, is:

$$R_{AA} = 1/N_{\text{coll}}(b=0) [(dN_H(b=0)/d^2p_\perp)|_{AA}/(dN_H/d^2p_\perp)|_{pp}],$$

where N_H is the number of hadrons counted, b is the impact parameter of the heavy-ion collision ($b=0$ means maximum centrality), AA labels nucleus-nucleus collision (pp for proton-proton) and N_{coll} is the number of nucleon-nucleon collisions occurred in AA . Such a quantity can be measured experimentally and calculated in a f/c model. The results are given in Fig. 1.

Fig. 1. The R_{AA} value as a function of $p_\perp$ for various hadrons. The solid lines are the theoretical results obtained in the f/c model.

As shown, R_{AA} has the ability to discriminate between mesons and baryons, as baryons tend to be higher in R_{AA} than mesons. The curves are instead the result of a theoretical calculation in a f/c model.

Let us consider here the case of the $f_0(980)$ scalar meson which also evades any standard $q\bar{q}$ interpretation. Two possibilities are examined: the f_0 is (1) a $q\bar{q}$, (2) a diquark-antidiquark meson (a molecular picture in which the f_0 is a kind of $K\bar{K}$ molecule is as old as the discovery of the f_0 itself). The $R_{AA}(f_0)$ at RHIC has not yet been analyzed. We provide a couple of theoretical curves to eventually compare to data. The X will be produced at the LHC where an $R_{AA}(X)$ analysis might be performed.

4 Conclusions

It would be an error if collaborations like BELLE and BaBar gave up the investigation of a possible $\Delta M \neq 0$ between the X produced in B^0 and B^+ , or the search for charged X 's. Clarifying the nature of the X and its 'similes' gives an opportunity to learn some new fundamental aspects of quantum chromodynamics.

Acknowledgements I wish to thank L. Maiani for fruitful and enjoyable collaboration and R.L. Jaffe and R. Faccini for many stimulating discussions. I conclude by thanking the organizers O. Nicrosini, G. Montagna and C. Vercesi for their kind invitation and their valuable work.
